

# Introduction to Dynamic Programming

## About me

- Carlos Gonzalez Oliver
- Email: carlos@ozeki.io
- Homepage: carlosoliver.co

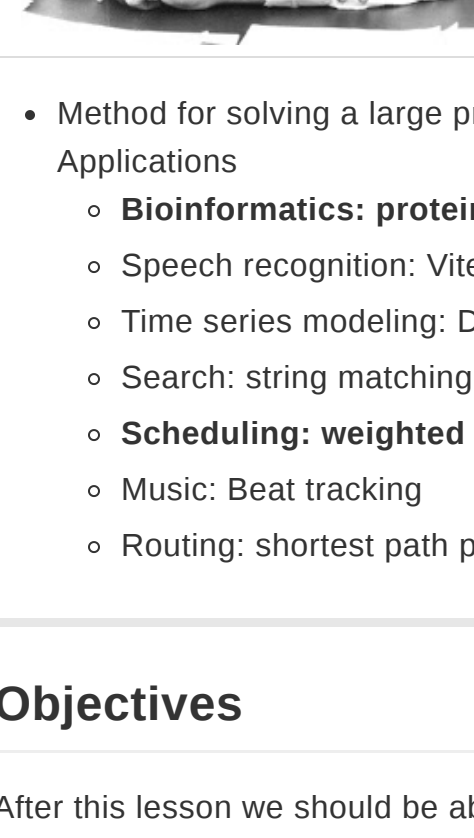

## My interests:

- Structural Bioinformatics
- Graph algorithms
- Representation learning

## Some questions I ask:

- How can we efficiently search through graph databases?
- What kinds of patterns can we discover in datasets of graphs?
- Can we model biological systems using efficient data structures to learn about how they function?

## Dynamic Programming (DP)

- Roger Bellman, 1950s, working at RAND Institute.
- Picked the name "Dynamic Programming" to please his boss.

- Method for solving a large problem by breaking it down into smaller sub-problems.
  - Applications
    - **Bioinformatics: protein and RNA folding, sequence alignment**
    - Speech recognition: Viterbi's algorithm
    - Time series modelling: Dynamic time warping
    - Search: string matching
    - **Scheduling: weighted interval**
    - Music: Beat tracking
    - Routing: shortest path problems

## Objectives

After this lesson we should be able to:

- ☐ Recognize the **ingredients** needed to solve a problem with DP.
- ☐ Write down and execute some simple DP algorithms.
- ☐ Be able to implement a DP algorithm for a real-world problem (homework).

## Basic Intuition

- What is:
  - $1+1+1+1+1+1=?$
- Now what is:
  - $1+1+1+1+1+1+1=?$

## First ingredient: Optimal Substructures

The optimal structure can be built by combining optimal solutions to smaller problems.

E.g. Fibonacci numbers

- $\text{Fib}(0)=0$
- $\text{Fib}(1)=1$
- $\text{Fib}(n)=\text{Fib}(n-1)+\text{Fib}(n-2)$

Recursive algorithm:

```
def fib(n):
    if n == 0:
        return 0
    if n == 1:
        return 1
    else:
        return fib(n-1) + fib(n-2)
```

Call tree  $\text{fib}(6)$ :

## Second ingredient: Overlapping Substructures

The same subproblem's solution is used multiple times.

```
def fib(n):
    if n == 0:
        return 0
    if n == 1:
        return 1
    else:
        return fib(n-1) + fib(n-2)
```

Call tree  $\text{fib}(6)$ :

## Can we do better?

$M\text{-fib}(n)$ :

## An example *without* overlapping subproblems.

**Binary Search:** Given a sorted array  $A$  and a query element, find the index where the query occurs.

```
def binary_search(A, left, right, query):
    if low > high:
        return None
    mid = (left + right) // 2
    if A[mid] == query:
        return j
    elif A[mid] > query:
        return binary_search(A, left, mid-1, query)
    else:
        return binary_search(A, mid+1, right, query)
```

Call tree  $\text{binary\_search}(A=[15, 22, 32, 36, 41, 63, 75], \text{left}=0, \text{right}=4, \text{query}=75)$ :

## Case study: Weighted Interval Scheduling

- **Input:**  $n$  requests, labeled  $\{1, \dots, n\}$ . Each request has a start time  $s_i$  and an end time  $t_i$ , and a **weight**  $v_i$ .
  - **Output:** a *compatible* subset  $S$  of  $\{1, \dots, n\}$  that maximizes  $\sum_{i \in S} v_i$ .
- $S$  is compatible iff all pairs of intervals in  $S$  are non-overlapping.
- Uses: resource allocation for computer systems, optimizing course selection.

Example:

```
Index
1 |----- v1 = 2 -----| p(1) = 0
2 |----- v2 = 4 -----| p(2) = 0
3 |----- v3 = 4 -----| p(3) = 1
4 |----- v4 = 7 -----| p(4) = 0
5 |----- v5 = 2 -----| p(5) = 3
6 |----- v6 = 1 -----| p(6) = 3
```

## False start: greedy approach

- From "previous" lectures we know the greedy approach to the unweighted IS problem gives the optimal solution (i.e. pick item with earliest ending time)

Counterexample:

The weights force us to consider all possible subproblems (i.e. local choice is not enough).

## A helper function

Let us sort all intervals by increasing *finish* time and let  $p(j)$  return the latest interval  $i$  that is still compatible with  $j$ .

Index

```
1 |----- v1 = 2 -----| p(1) = 0
2 |----- v2 = 4 -----| p(2) = 0
3 |----- v3 = 4 -----| p(3) = 1
4 |----- v4 = 7 -----| p(4) = 0
5 |----- v5 = 2 -----| p(5) = 3
6 |----- v6 = 1 -----| p(6) = 3
```

## First ingredient: Optimal Substructure?

- Consider  $O_j$  to be the *optimal* set of requests over all items  $j$ .

- Also consider the *weight* of the best solution up to  $j$  as  $\text{OPT}(j)$ .

- There are two cases for the last request,  $j$ :

Case 1

Case 2

## Optimal Substructure

Let  $\text{OPT}(j)$  be the total weight of the optimal over intervals up to  $j$ .

We can now write an expression for computing  $\text{OPT}(j)$ :

Ingredients

- ☒ Optimal Substructure
- ☐ Overlapping Subproblems

## First algorithm

Now we can write down a recursive algorithm that gives us the maximum weight over  $1, \dots, n$ .

$\text{compute\_OPT}(j)$ :

## Ingredient 2: Overlapping Substructures

Let's build the execution tree for our recursive algorithm on this example:

Index

```
1 |----- v1 = 2 -----| p(1) = 0
2 |----- v2 = 4 -----| p(2) = 0
3 |----- v3 = 4 -----| p(3) = 1
4 |----- v4 = 7 -----| p(4) = 0
5 |----- v5 = 2 -----| p(5) = 3
6 |----- v6 = 1 -----| p(6) = 3
```

$\text{compute\_OPT}(6)$ :

Runtime:

Ingredients

- ☒ Optimal Substructure
- ☒ Overlapping Subproblems

## Memoization

- Key idea in DP: remember solutions to sub-problems you already computed.

New algo:  $M\text{-compute\_OPT}(j)$

## Are we done?

- Recall  $\text{OPT}(j)$  is just a number, we want the *set* of intervals with the score  $\text{OPT}(j)$ ... i.e.  $O_j$ .
- **Traceback** is a key idea in DP. We reconstruct the solution backwards from the  $M$  array using the recurrence.
- **Observation:** We know that an interval  $j$  belongs to  $O_j$  if:

Now our DP execution has two steps:

1. Fill  $M$
2. Reconstruct solution from  $M[n]$

## Full Example

Index

```
1 |----- v1 = 2 -----| p(1) = 0
2 |----- v2 = 4 -----| p(2) = 0
3 |----- v3 = 4 -----| p(3) = 1
4 |----- v4 = 7 -----| p(4) = 0
5 |----- v5 = 2 -----| p(5) = 3
6 |----- v6 = 1 -----| p(6) = 3
```

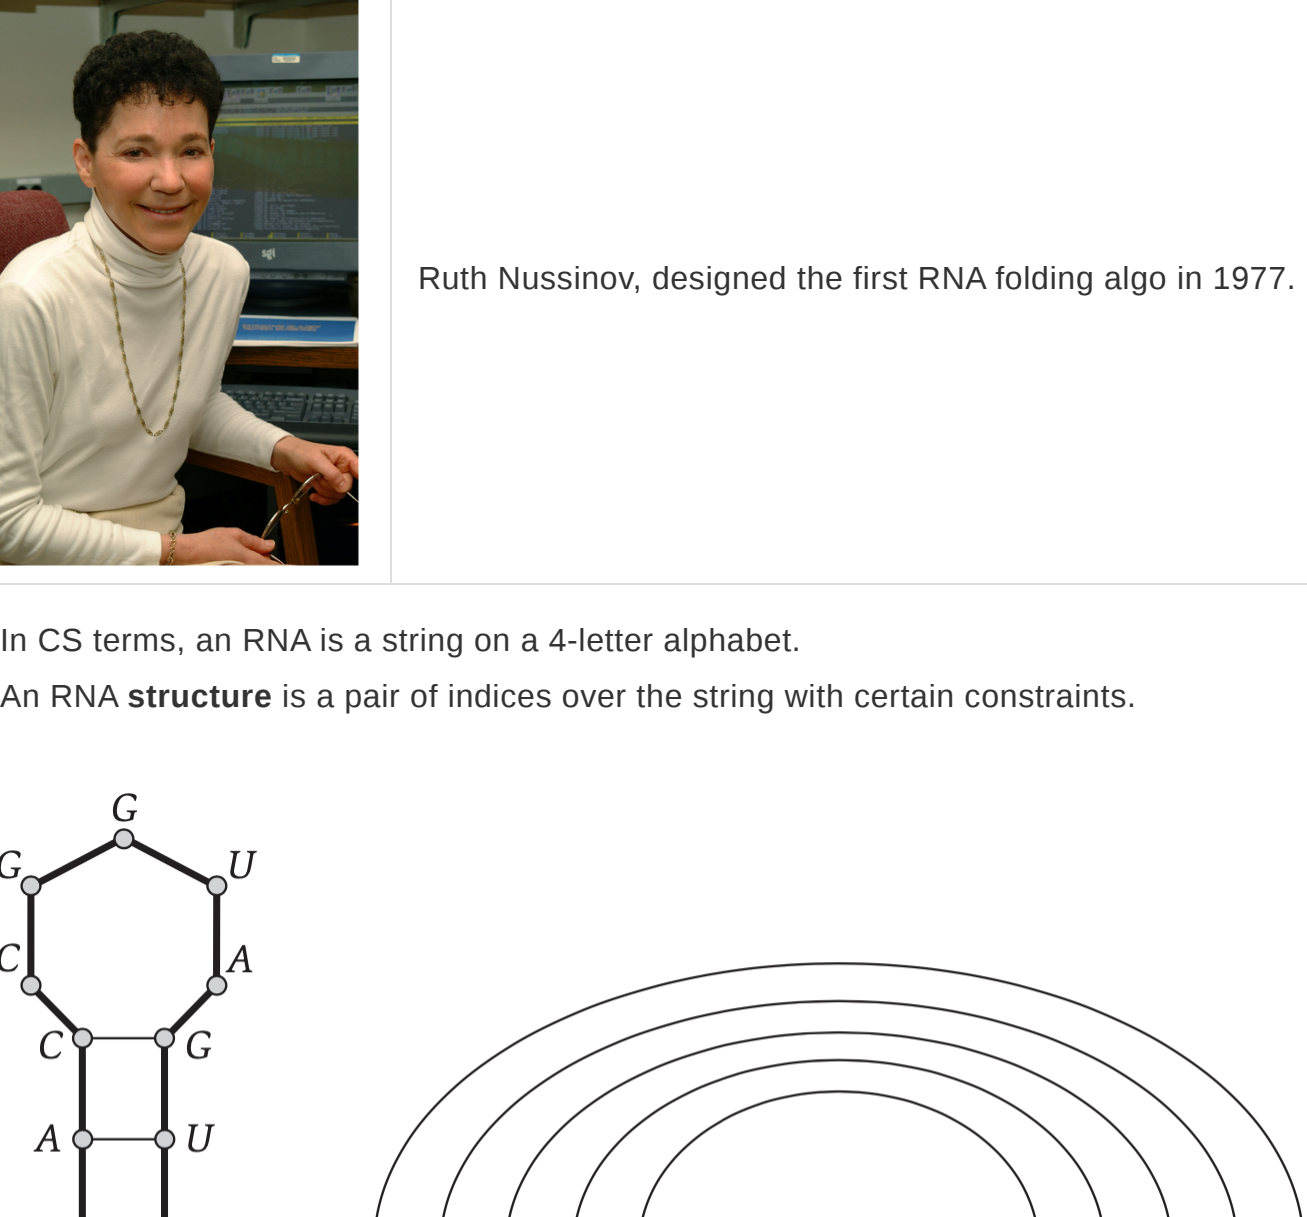

Fill  $M$  and get  $O_n$ :

## Recap

- Dynamic Programming works well when we have a problem structure such that:
  - Combining sub-problems solves the whole problem
  - Sub-problems overlap
- We can often reduce runtime complexity from exponential to polynomial or linear.
- Steps to solving a problem with DP:
  - Define subproblems:
    - $\text{fib}(n-1)$  and  $\text{fib}(n-2)$  are subproblems of  $\text{fib}(n)$
  - Write down the recurrence that relates subproblems.
    - $\text{fib}(n) = \text{fib}(n-1) + \text{fib}(n-2)$
  - Recognize and solve the base cases.
    - $\text{fib}(0) = 1, \text{fib}(1) = 1$
  - Implement a solving methodology. (e.g. memoization, tabulation is also an option)

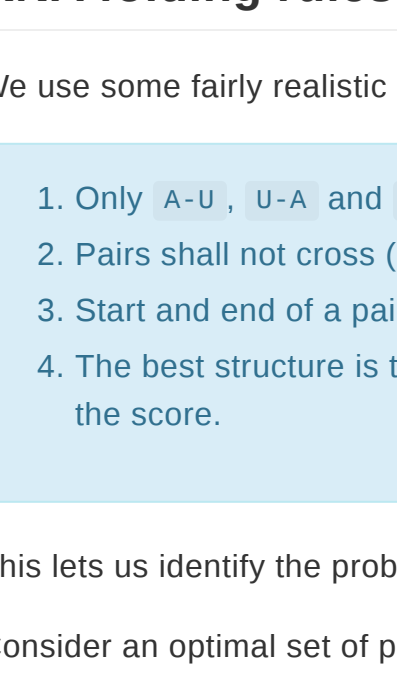

## General interest: RNA folding

- RNA molecules are essential to all living organisms.
- Knowing the sequence is easy but not so informative, knowing the structure is hard but tells us a lot about the molecule's function.

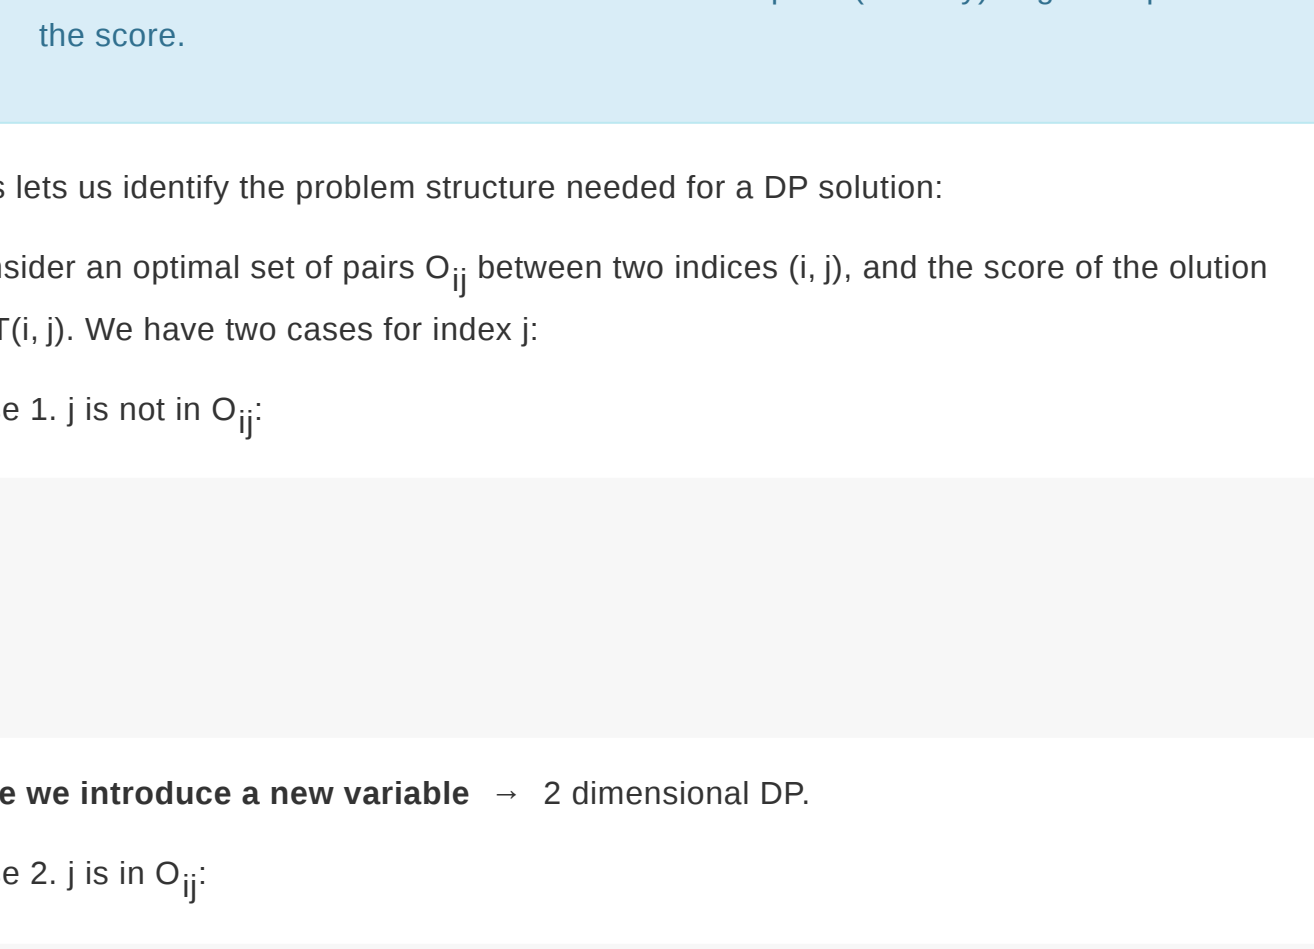

## A Sketch of Nussinov's Algorithm

- First attempt at solving this problem

Ruth Nussinov, designed the first RNA folding algo in 1977.

- In CS terms, an RNA is a string on a 4-letter alphabet.
- An RNA **structure** is a pair of indices over the string with certain constraints.

## RNA folding rules

We use some fairly realistic constraints on admissible structures:

1. Only  $A-U$ ,  $U-A$  and  $C-G$ ,  $G-C$  form pairs
2. Pairs shall not cross (nestedness).
3. Start and end of a pair should be separated by at least 0 spaces (remove steric clashes).
4. The best structure is the one that forms the most pairs (stability). e.g each pair adds 1 to the score.

This lets us identify the problem structure needed for a DP solution:

Consider an optimal set of pairs  $O_{ij}$  between two indices  $(i, j)$ , and the score of the solution  $\text{OPT}(i, j)$ . We have two cases for index  $j$ :

Case 1.  $j$  is not in  $O_{ij}$

Case 2.  $j$  is in  $O_{ij}$

## Ingredients?

- ☐ Optimal substructures
- ☐ Overlapping subproblems

From this we can build our recurrence that fills the table up to  $\text{OPT}(L, L)$ .

Bonus Questions: What is the runtime for filling the table?

If you want an exercise sheet to learn how to implement this send me an email  
carlos@ozeki.io.
